

# React

Is React a framework or a library?

A framework is used for building and deploying an application quickly. When we use a framework, we can use resources to facilitate faster development and a greater user experience.

A library is a collection of reusable, compiled and tested code used to enhance the functionality of an application.

React is referred to as unopinionated because there are lots of options to do something and we have to choose our tools carefully and create a proper design system for a specific project. That is why React is called a library, not a framework.

Writing a heading in HTML vs JS

Ex: `<html>`  
`<body>`  
`<h1> Hello Everyone </h1>`  
`</body>`  
`</html>`

Ex: html file  
`<div id = 'root'>`  
`</div>`  
`<body>`  
`<script>`

```
const document = createElement('h1');  
heading = document.createElement('h1');  
(heading.innerHTML = 'Hello Everyone');  
const root = document.appendChild(heading)  
const content = document.getElementById('root')  
content.appendChild(heading)
```

## Writing a heading in React:

```
const heading = React.createElement("h1", {}, "Hello World");
```

↓  
Here `h1` is core HTML element, hence we are using `React`

```
const root = ReactDOM.createRoot(document.getElementById("root"))
```

↓  
Here we are manipulating the DOM by using `ReactDOM` and creating a root in the `div` by the id `root`

```
root.render(heading);
```

## Use of React:

In general, when we perform any DOM manipulation operation on the browser like clicking a button, we are indirectly making changes in the DOM tree. Usually these are costly operations.

So, frameworks like `React` try to optimize it.

↳

```
const heading = React.createElement("h1", {id: "heading"}, "Hello World");
```

↓  
This object is used for specifying attributes for tags.

↳ `React.createElement` creates a javascript object which is a `React element` (it is not an `h1` tag here)

```
console.log(heading)
```

↳ This is that object above

↳ root.render()

↳ Basically takes the object and renders in the DOM.

### Creating nested HTML structure inside React!

```
<div id = "parent">
```

```
<div id = "child">
```

```
<h1> I am h1 tag </h1>
```

```
</div>
```

```
</div>
```

↳

```
const parent = React.createElement("div", {id: "parent"},  
  React.createElement("div", {id: "child"},  
    React.createElement("h1", {}, "I am h1 tag"));
```

In order to create two elements at the same level, we need to combine the child elements in an array.

```
<h1> I am h1 tag </h1>
```

```
<h2> I am h2 tag </h2>
```

```
const parent = React.createElement("div", {id: "parent"},  
  React.createElement("div", {id: "child"},  
    [React.createElement("h1", {}, "I am h1 tag"),  
     React.createElement("h2", {}, "I am h2 tag")])
```

→ If there are more nested elements in HTML, then this React code becomes complicated to understand. Hence there is a concept called JSX.

## Note:

In the `index.html` file created before, we have placed 3 script tags.

Here the sequence of those files matters before because, we cannot place `App.js` file before those `cdn` files as `React` is not specified in that situation.

so `cdn` files first, then only `App.js`.

↳ In the previous example, on this line

`root.render(parent)`

This renders the parent object into the `div` section present in `index.html` for now or initially, the `div` section is empty.

So whatever parent has, is rendered onto `div`.

However if there are any content already present in `div` before rendering. Then the initial content is "completely" replaced and the newly created "parent object" is rendered.

↳ It is very clear in these examples, that we can apply `React` to a small portion of code and it works fine. This makes `React` library instead of a full fledged framework.
